## Introduction

### 1.1 Overview

The rapid advancement of next-generation sequencing (NGS) technologies has transformed genomic research by enabling high-throughput and cost-effective DNA analysis (Metzker, 2010). Among current platforms, Illumina sequencing remains the most widely adopted, capable of producing millions of short reads that can be assembled into reference genomes or analyzed for genetic variation (Bentley et al., 2008; Glenn, 2011). Despite its high base-calling accuracy, Illumina sequencing is prone to artifacts introduced during library preparation, particularly polymerase chain reaction (PCR)-induced chimeras, which are artificial hybrid sequences that do not exist in the true genome (Judo, Wedel, & Wilson, 1998).

PCR chimeras form when incomplete extension products from one template

anneal to an unrelated DNA fragment and are extended, creating recombinant reads (Qiu et al., 2001). In mitochondrial genome assembly, such artifacts are especially problematic because the mitochondrial genome is small, circular, and often repetitive (Boore, 1999; Cameron, 2014). Even a small number of chimeric or mis-joined reads can reduce assembly contiguity and introduce false junctions during organelle genome reconstruction (Dierckxsens, Mardulyn, & Smits, 2017; Hahn, Bachmann, & Chevreux, 2013; Jin et al., 2020). Existing assembly tools such as GetOrganelle and MITObim assume that input reads are largely free of such artifacts (Hahn et al., 2013; Jin et al., 2020). Consequently, undetected chimeras may produce fragmented assemblies or misidentified organellar boundaries. To ensure accurate reconstruction of mitochondrial genomes, a reliable and automated method for detecting and filtering PCR-induced chimeras before assembly is essential.

This study focuses on mitochondrial sequencing data from the genus *Sardinella*, a group of small pelagic fishes widely distributed in Philippine waters. Among them, *Sardinella lemuru* (Bali sardinella) is one of the country’s most abundant and economically important species, providing protein and livelihood to coastal communities (Labrador, Agmata, Palermo, Ravago-Gotanco, & Pante, 2021; Willette, Bognot, Mutia, & Santos, 2011). Accurate mitochondrial assemblies are critical for understanding its population genetics, stock structure, and evolutionary history. However, assembly pipelines often encounter errors or fail to complete due to undetected chimeric reads. To address this gap, this research introduces **MitoChime**, a machine-learning pipeline designed to detect and filter PCR-induced chimeric reads using both alignment- and sequence-derived statistical features. The tool aims to provide bioinformatics laboratories, particularly the

96 Philippine Genome Center Visayas, with an efficient, interpretable, and resource-  
97 optimized solution for improving mitochondrial genome reconstruction.

## 98 1.2 Problem Statement

99 While NGS technologies have revolutionized genomic data acquisition, the ac-  
100 curacy of mitochondrial genome assembly remains limited by artifacts produced  
101 during PCR amplification. These chimeric reads can distort assembly graphs and  
102 cause misassemblies, with especially severe effects in small, circular mitochon-  
103 drial genomes (Boore, 1999; Cameron, 2014). Existing assembly pipelines such  
104 as GetOrganelle, MITObim, and NOVOPlasty assume that sequencing reads are  
105 free of such artifacts (Dierckxsens et al., 2017; Hahn et al., 2013; Jin et al., 2020).  
106 At the Philippine Genome Center Visayas, several mitochondrial assemblies have  
107 failed or yielded incomplete contigs despite sufficient coverage, suggesting that  
108 undetected chimeric reads compromise assembly reliability. Meanwhile, exist-  
109 ing chimera-detection tools such as UCHIME and VSEARCH were developed  
110 primarily for amplicon-based microbial community analysis and rely heavily on  
111 reference or taxonomic comparisons (Edgar, Haas, Clemente, Quince, & Knight,  
112 2011; Rognes, Flouri, Nichols, Quince, & Mahé, 2016). These approaches are un-  
113 suitable for single-species organellar data, where complete reference genomes are  
114 often unavailable. Therefore, there is a pressing need for a reference-independent,  
115 data-driven tool capable of automatically detecting and filtering PCR-induced  
116 chimeras in mitochondrial sequencing datasets.

## 117 1.3 Research Objectives

### 118 1.3.1 General Objective

119 To develop and evaluate a machine-learning-based pipeline (MitoChime) capable  
120 of detecting PCR-induced chimeric reads in *Sardinella* mitochondrial sequencing  
121 data to improve the accuracy of mitochondrial genome assembly.

### 122 1.3.2 Specific Objectives

123 Specifically, the researchers aim to:

- 124 1. Construct empirical as well as simulated *Sardinella* Illumina paired-end  
125 datasets containing both clean and PCR-induced chimeric reads.
- 126 2. Extract alignment- and sequence-based features (e.g., k-mer composition,  
127 junction complexity, split-alignment counts) from both clean and chimeric  
128 reads.
- 129 3. Train, validate, and compare supervised machine-learning models (e.g., Ran-  
130 dom Forest, XGBoost) for classifying reads as clean or chimeric.
- 131 4. Determine feature importance and identify the most informative indicators  
132 of PCR-induced chimerism.
- 133 5. Integrate the optimized classifier into a modular and interpretable pipeline  
134 deployable on standard computing environments at PGC Visayas.

## 135 1.4 Scope and Limitations of the Research

136 This study focuses on detecting PCR-induced chimeric reads in Illumina paired-  
137 end mitochondrial sequencing data from *Sardinella* species. The work emphasizes  
138 `wgsim` simulations and selected empirical data obtained from open-access genomic  
139 repositories such as the National Center for Biotechnology Information (NCBI).  
140 The study excludes naturally occurring chimeras, nuclear mitochondrial pseudo-  
141 genes (NUMTs), and large-scale structural rearrangements in nuclear genomes.  
142 Feature extraction prioritizes interpretable, shallow statistics and alignment met-  
143 rics rather than deep-learning embeddings to ensure transparency and computa-  
144 tional efficiency. Testing on long-read platforms (e.g., Nanopore, PacBio) and  
145 other taxa lies beyond the project’s scope. The resulting pipeline will serve as a  
146 foundation for future, broader chimera-detection frameworks applicable to diverse  
147 organellar genomes.

## 148 1.5 Significance of the Research

149 This research provides both methodological and practical contributions to mi-  
150 tochondrial genomics and bioinformatics. First, MitoChime enhances assembly  
151 accuracy by filtering PCR-induced chimeras prior to genome assembly, thereby  
152 improving the contiguity and correctness of *Sardinella* mitochondrial genomes.  
153 Second, it promotes automation and reproducibility by replacing subjective man-  
154 ual curation with a data-driven, machine-learning-based workflow. Third, the  
155 pipeline demonstrates computational efficiency through its design, enabling im-  
156 plementation on modest computing infrastructures commonly available in regional

157 laboratories. Beyond technical improvements, MitoChime contributes to local ca-  
158 pacity building by strengthening expertise in bioinformatics and machine-learning  
159 integration, aligning with the mission of the Philippine Genome Center Visayas.  
160 Finally, accurate mitochondrial assemblies are vital for fisheries management,  
161 population genetics, and biodiversity conservation, providing reliable genomic re-  
162 sources for species such as *Sardinella*. Through these contributions, MitoChime  
163 advances the reliability of mitochondrial genome reconstruction and supports sus-  
164 tainable, data-driven research in Philippine genomics.

# 165 Chapter 2

## 166 Review of Related Literature

167 This chapter presents an overview of the literature relevant to the study. It  
168 discusses the biological and computational foundations underlying mitochondrial  
169 genome analysis and assembly, as well as existing tools, algorithms, and techniques  
170 related to chimera detection and genome quality assessment. The chapter aims to  
171 highlight the strengths, limitations, and research gaps in current approaches that  
172 motivate the development of the present study.

### 173 2.1 The Mitochondrial Genome

174 Mitochondrial genome (mtDNA) is a small, typically circular molecule found in  
175 most eukaryotes. It encodes essential genes involved in oxidative phosphorylation  
176 and energy metabolism. Because of its conserved structure and maternal inher-  
177 itance, mtDNA has become a valuable genetic marker for studies in evolution,  
178 population genetics, and phylogenetics (Anderson et al., 1981; Boore, 1999). In

179 animal species, the mitochondrial genome ranges from 15–20 kilobase and contains  
180 13 protein-coding genes, 22 tRNAs, and two rRNAs arranged compactly without  
181 introns (Gray, 2012). In comparison to nuclear DNA the ratio of the number  
182 of copies of mtDNA is higher and has relatively simple organization which make  
183 it particularly suitable for genome sequencing and assembly studies (Dierckxsens  
184 et al., 2017). Moreover, mitochondrial genomes provide crucial insights into evo-  
185 lutionary relationships among species and are increasingly used for testing new  
186 genomic assembly and analysis methods.

### 187 **2.1.1 Mitochondrial Genome Assembly**

188 Mitochondrial genome assembly refers to the reconstruction of the complete mito-  
189 chondrial DNA (mtDNA) sequence from raw or fragmented sequencing reads. It is  
190 conducted to obtain high-quality, continuous representations of the mitochondrial  
191 genome that can be used for a wide range of analyses, including species identi-  
192 fication, phylogenetic reconstruction, evolutionary studies, and investigations of  
193 mitochondrial diseases. Because mtDNA evolves relatively rapidly and is mater-  
194 nally inherited, its assembled sequence provides valuable insights into population  
195 structure, lineage divergence, and adaptive evolution across taxa (Boore, 1999).  
196 Compared to nuclear genome assembly, assembling the mitochondrial genome is  
197 often considered more straightforward but still encounters distinct technical chal-  
198 lenges such as sequencing errors, low coverage regions, and chimeric reads that can  
199 distort the final assembly, leading to incomplete or misassembled genomes. These  
200 errors can propagate into downstream analyses, emphasizing the need for robust  
201 chimera detection and sequence validation methods in mitochondrial genome re-

202 search.

## 203 **2.2 PCR Amplification and Chimera Formation**

204 Polymerase Chain Reaction (PCR) plays an important role in next-generation  
205 sequencing (NGS) library preparation, as it amplifies target DNA fragments for  
206 downstream analysis. However, the amplification process can also introduce arti-  
207 facts that affect data accuracy, one of them being the formation of chimeric se-  
208 quences. Chimeras typically arise when incomplete extension occurs during a PCR  
209 cycle. This causes the DNA polymerase to switch from one template to another  
210 and generate hybrid recombinant molecules (Judo et al., 1998). Artificial chimeras  
211 are produced through such amplification errors, whereas biological chimeras oc-  
212 cur naturally through genomic rearrangements or transcriptional events. These  
213 biological chimeras can have functional roles and may encode tissue-specific novel  
214 proteins that link to cellular processes or diseases (Frenkel-Morgenstern et al.,  
215 2012).

216 In the context of amplicon-based sequencing, PCR-induced chimeras can sig-  
217 nificantly distort analytical outcomes. Their presence artificially inflates estimates  
218 of genetic or microbial diversity and may cause misassemblies during genome re-  
219 construction. (Qin et al., 2023) has reported that chimeric sequences may account  
220 for more than 10% of raw reads in amplicon datasets. This artifact tends to be  
221 most prominent among rare operational taxonomic units (OTUs) or singletons,  
222 which are sometimes misinterpreted as novel diversity, which further causes the  
223 complication of microbial diversity analyses (Gonzalez, Zimmermann, & Saiz-

224 Jimenez, 2004). Moreover, the likelihood of chimera formation has been found to  
225 vary with the GC content of target sequences, with lower GC content generally  
226 associated with a reduced rate of chimera generation (Qin et al., 2023).

### 227 **2.2.1 Effects of Chimeric Reads on Organelle Genome As-** 228 **sembly**

229 In mitochondrial DNA (mtDNA) assembly workflows, PCR-induced chimeras pose  
230 additional challenges. Assembly tools such as GetOrganelle and MitoBeam, which  
231 operate under the assumption of organelle genome circularity, are vulnerable when  
232 chimeric reads disrupt this circular structure. Such disruptions can lead to assem-  
233 bly errors or misassemblies (Bi et al., 2024). These artificial sequences interfere  
234 with the assembly graph, which makes it more difficult to accurately reconstruct  
235 mitochondrial genomes. In addition, these artifacts propagate false variants and  
236 erroneous annotations in genomic data. Hence, determining and minimizing PCR-  
237 induced chimera formation is vital for improving the quality of mitochondrial  
238 genome assemblies, and ensuring the reliability of amplicon sequencing data.

## 2.3 Existing Traditional Approaches for Chimera Detection

Several computational tools have been developed to identify chimeric sequences in NGS datasets. These tools generally fall into two categories: reference-based and de novo approaches. Reference-based chimera detection, also known as database-dependent detection, is one of the earliest and most widely used computational strategies for identifying chimeric sequences in amplicon-based microbial community studies. These methods rely on the comparison of each query sequence against a curated, high-quality database of known, non-chimeric reference sequences to determine whether the query can be more plausibly explained as a composite or a mosaic of two or more reference sequences rather than as a genuine biological variant (Edgar et al., 2011).

On the other hand, the De novo chimera detection, also referred to as reference-free detection, represents an alternative computational paradigm that identifies chimeric sequences without reliance on external reference databases. Instead of comparing each query sequence to a curated collection of known, non-chimeric sequences, de novo methods infer chimeras based on internal relationships among the sequences present within the dataset itself. This approach is particularly advantageous in studies of novel, under explored, or taxonomically diverse microbial communities where comprehensive reference databases are unavailable or incomplete (Edgar, 2016; Edgar et al., 2011). The underlying assumption on this method operates on the key biological principle that true biological sequences are generally more abundant than chimeric artifacts. During PCR amplification, authentic sequences are amplified early and tend to dominate the read pool, while

263 chimeric sequences form later resulting in the tendency to appear at lower relative  
264 abundances compared to their true parental sequences. As such, the abundance  
265 hierarchy is formed by treating the most abundant sequences as supposed parents  
266 and testing whether less abundant sequences can be reconstructed as mosaics of  
267 these dominant templates. In addition to abundance, de novo algorithms assess  
268 compositional and structural similarity among sequences, examining whether cer-  
269 tain regions of a candidate sequence align more closely with one high-abundance  
270 sequence and other regions with a different one.

271 Both reference-based and de novo approaches are complementary rather than  
272 mutually exclusive. Reference-based methods provide stability and reproducibility  
273 when curated databases are available, whereas de novo methods offer flexibility  
274 and independence for novel or highly diverse communities. In practice, many  
275 modern bioinformatics pipelines combine both paradigms sequentially: an initial  
276 de novo step identifies dataset-specific chimeras, followed by a reference-based pass  
277 that removes remaining artifacts relative to established databases (Edgar, 2016).  
278 These two methods of detection form the foundation of tools such as UCHIME  
279 and later UCHIME2, exemplified by the dual capability of providing both modes  
280 within a unified computational framework.

### 281 **2.3.1 UCHIME**

282 Developed by Edgar et al. (Edgar et al., 2011), UCHIME is one of the most widely  
283 used computational tools for detecting chimeric sequences in amplicon sequencing  
284 data. The UCHIME algorithm detects chimeras by evaluating how well a query  
285 sequence (Q) can be explained as a mosaic of two parent sequences (A and B)

286 from a reference database. The query sequence is first divided into four non-  
287 overlapping segments or chunks. Each chunk is independently searched against a  
288 reference database that is assumed to be free of chimeras. The best matches to  
289 each segment are collected, and from these results, two candidate parent sequences  
290 are identified, typically the two sequences that best explain all chunks of the query.  
291 Then a three-way alignment among the query (Q) and the two parent candidates  
292 (A and B) is done. From this alignment, UCHIME attempts to find a chimeric  
293 model (M) which is a hypothetical recombinant sequence formed by concatenating  
294 fragments from A and B that best match the observed Q

## 295 **Chimeric Alignment and Scoring**

296 To decide whether a query is chimeric, UCHIME computes several alignment-  
297 based metrics between Q, its top hit (T, the most similar known sequence), and  
298 the chimeric model (M). The key differences are measured as: dQT or the number  
299 of mismatches between the query and the top hit as well as dQM or the number  
300 of mismatches between the query and the chimeric model. From these, a chimera  
301 score is calculated to quantify how much better the chimeric model fits the query  
302 compared to a single parent. If the model's similarity to Q exceeds a defined  
303 threshold (typically  $\geq 0.8\%$  better identity), the sequence is reported as chimeric.  
304 A higher score indicates stronger evidence of chimerism, while lower scores suggest  
305 that the sequence is more likely to be authentic.

306 In de novo mode, UCHIME applies an abundance-driven strategy. Only se-  
307 quences at least twice as abundant as the query are considered as potential parents.  
308 Non-chimeric sequences identified at each step are added iteratively to a growing

309 internal database for subsequent queries.

## 310 **Limitations of UCHIME**

311 Although UCHIME was a significant advancement in chimera detection, it has  
312 notable limitations. According to (Edgar, 2016) and the UCHIME practical notes  
313 (Edgar, n.d), many of the accuracy results reported in the original 2011 paper  
314 were overly optimistic due to unrealistic benchmark designs that assumed com-  
315 plete reference coverage and perfect sequence quality. In practice, UCHIME’s  
316 accuracy can decline when: (1) The reference database is incomplete or contains  
317 erroneous entries. (2) Low-divergence chimeras are present, as these closely resem-  
318 ble genuine biological variants. (3) Sequence datasets include residual sequencing  
319 errors, leading to spurious alignments or misidentification; and (4) The abundance  
320 ratio between parent and chimera is distorted by amplification bias. Additionally,  
321 UCHIME tends to misclassify sequences as non-chimeric when parent sequences  
322 are missing from the database. These limitations motivated the development of  
323 UCHIME2.

## 324 **2.3.2 UCHIME2**

325 To overcome the limitations of its predecessor, UCHIME2 (Edgar, 2016) intro-  
326 duced several methodological and algorithmic refinements that significantly en-  
327 hanced the accuracy and reliability of chimera detection. One major improve-  
328 ment lies in its approach to uncertainty handling. In earlier versions, sequences  
329 with limited reference support were often incorrectly classified as non-chimeric,

330 increasing the likelihood of false negatives. UCHIME2 addresses this issue by  
331 designating such ambiguous sequences as “unknown,” thereby providing a more  
332 conservative and reliable classification framework.

333 Another notable advancement is the introduction of multiple application-  
334 specific modes that allow users to tailor the algorithm’s performance to the  
335 characteristics of their datasets. The following parameter presets: denoised,  
336 balanced, sensitive, specific, and high-confidence, enable researchers to optimize  
337 the balance between sensitivity and specificity according to the goals of their  
338 analysis.

339 In comparative evaluations, UCHIME2 demonstrated superior detection per-  
340 formance, achieving sensitivity levels between 93% and 99% and lower overall  
341 error rates than earlier versions or other contemporary tools such as DECIPHER  
342 and ChimeraSlayer. Despite these advances, the study also acknowledged a fun-  
343 damental limitation in chimera detection: complete error-free identification is  
344 theoretically unattainable. This is due to the presence of “perfect fake models,”  
345 wherein genuine non-chimeric sequences can be perfectly reconstructed from other  
346 reference fragments. This underscore the uncertainty in differentiating authentic  
347 biological sequences from artificial recombinants based solely on sequence similar-  
348 ity, emphasizing the need for continued methodological refinement and cautious  
349 interpretation of results.

### 350 2.3.3 CATch

351 Early chimera detection programs such as UCHIME (Edgar et al., 2011) relied on  
352 alignment-based and abundance-based heuristics to identify hybrid sequences in  
353 amplicon data. However, researchers soon observed that different algorithms often  
354 produced inconsistent predictions. A sequence might be identified as chimeric by  
355 one tool but classified as non-chimeric by another, resulting in unreliable filtering  
356 outcomes across studies.

357 To address these inconsistencies, (Mysara, Saeys, Leys, Raes, & Monsieurs,  
358 2015) developed the Classifier for Amplicon Tool Chimeras (CATCh), which rep-  
359 resents the first ensemble machine learning system designed for chimera detection  
360 in 16S rRNA amplicon sequencing. Rather than depending on a single detec-  
361 tion strategy, CATCh integrates the outputs of several established tools, includ-  
362 ing UCHIME, ChimeraSlayer, DECIPHER, Pintail, and Perseus. The individual  
363 scores and binary decisions generated by these tools are used as input features for  
364 a supervised learning model. The algorithm employs a Support Vector Machine  
365 (SVM) with a Pearson VII Universal Kernel (PUK) to determine optimal weight-  
366 ings among the input features and to assign each sequence a probability of being  
367 chimeric.

368 Benchmarking in both reference-based and de novo modes demonstrated signif-  
369 icant performance improvements. CATCh achieved sensitivities of approximately  
370 85 percent in reference-based mode and 92 percent in de novo mode, with corre-  
371 sponding specificities of approximately 96 percent and 95 percent. These results  
372 indicate that CATCh detected 7 to 12 percent more chimeras than any individual  
373 algorithm while maintaining high precision. Integration of CATCh into amplicon-

374 processing pipelines also reduced operational taxonomic unit (OTU) inflation by  
375 23 to 35 percent, producing diversity estimates that more closely reflected true  
376 community composition.

### 377 **2.3.4 ChimPipe**

378 Among the available tools for chimera detection, ChimPipe is a bioinformat-  
379 ics pipeline developed to identify chimeric sequences such as fusion genes and  
380 transcription-induced chimeras from paired-end RNA sequencing data. It uses  
381 both discordant paired-end reads and split-read alignments to improve the ac-  
382 curacy and sensitivity of detecting fusion genes, trans-splicing events, and read-  
383 through transcripts (Rodriguez-Martin et al., 2017). By combining these two  
384 sources of information, ChimPipe achieves better precision than methods that  
385 depend on a single type of signal.

386 The pipeline works with many eukaryotic species that have available genome  
387 and annotation data, making it a versatile tool for studying chimera evolution  
388 and transcriptome structure (Rodriguez-Martin et al., 2017). It can also predict  
389 multiple isoforms for each gene pair and identify breakpoint coordinates that are  
390 useful for reconstructing and verifying chimeric transcripts. Tests using both  
391 simulated and real datasets have shown that ChimPipe maintains high accuracy  
392 and reliable performance.

393 ChimPipe’s modular design lets users adjust parameters to fit different se-  
394 quencing protocols or organism characteristics. Experimental results have con-  
395 firmed that many chimeric transcripts detected by the tool correspond to func-

396 tional fusion proteins, showing its value for understanding chimera biology and  
397 its potential applications in disease research (Rodriguez-Martin et al., 2017).

## 398 **2.4 Machine Learning Approaches for Chimera** 399 **and Sequence Quality Detection**

400 Traditional chimera detection tools rely primarily on heuristic or alignment-based  
401 rules. Recent advances in machine learning (ML) have demonstrated that mod-  
402 els trained on sequence-derived features can effectively capture compositional and  
403 structural patterns in biological sequences. Although most existing ML systems  
404 such as those used for antibiotic resistance prediction, taxonomic classification,  
405 or viral identification are not specifically designed for chimera detection, they  
406 highlight how data-driven models can outperform similarity-based heuristics by  
407 learning intrinsic sequence signatures. In principle, ML frameworks can inte-  
408 grate diverse indicators such as k-mer frequencies, GC-content variation, and  
409 split-alignment metrics to identify subtle anomalies that may indicate a chimeric  
410 origin (Arango et al., 2018; Liang, Bible, Liu, Zou, & Wei, 2020; Ren et al., 2020).

### 411 **2.4.1 Feature-Based Representations of Genomic Se-** 412 **quences**

413 In genomic analysis, feature extraction converts DNA sequences into numerical  
414 representations suitable for ML algorithms. A common approach is k-mer fre-  
415 quency analysis, where normalized k-mer counts form the feature vector (Vervier,

2015). These features effectively capture local compositional patterns that often differ between authentic and chimeric reads. In particular, deviations in k-mer profiles between adjacent read segments can serve as a compositional signature of template-switching events. Additional descriptors such as GC content and sequence entropy can further distinguish sequence types; in metagenomic classification and virus detection, k-mer-based features have shown strong performance and robustness to noise (Ren et al., 2020; Vervier, 2015). For chimera detection specifically, abrupt shifts in GC or k-mer composition along a read can indicate junctions between parental fragments. Windowed feature extraction enables models to capture these discontinuities that rule-based algorithms may overlook.

Machine learning models can also leverage alignment-derived features such as the frequency of split alignments, variation in mapping quality, and local coverage irregularities. Split reads and discordant read pairs are classical signatures of genomic junctions and have been formalized in probabilistic frameworks for structural-variant discovery that integrate multiple evidence types (Layer, Hall, & Quinlan, 2014). Similarly, long-read tools such as Sniffles employ split-alignment and coverage anomalies to accurately localize breakpoints (Sedlazeck et al., 2018). Modern aligners such as Minimap2 (Li, 2018) output supplementary (SA tags) and secondary alignments as well as chaining and alignment-score statistics that can be summarized into quantitative predictors for machine-learning models. These alignment-signal features are particularly relevant to PCR-induced mitochondrial chimeras, where template-switching events produce reads partially matching distinct regions of the same or related genomes. Integrating such cues within a supervised-learning framework enables artifact detection even in datasets lacking complete or perfectly assembled references.

441 A further biologically grounded descriptor is micro-homology length at puta-  
442 tive junctions. Micro-homology refers to short, shared sequences (often in the  
443 range of a few to tens of base pairs) that are near breakpoints and mediate  
444 non-canonical repair or template-switch mechanisms. Studies of double strand  
445 break repair and structural variation have demonstrated that the length of micro-  
446 homology correlates with the likelihood of micro-homology-mediated end joining  
447 (MMEJ) or fork-stalled template-switching pathways (Sfeir & Symington, 2015).  
448 In the context of PCR-induced chimeras, template switching during amplifica-  
449 tion often leaves short identical sequences at the junction of two concatenated  
450 fragments. Quantifying the longest exact suffix-prefix overlap at each candidate  
451 breakpoint thus provides a mechanistic signature of chimerism and complements  
452 both compositional (k-mer) and alignment (SA count) features.

## 453 2.5 Synthesis of Chimera Detection Approaches

454 To provide an integrated overview of the literature discussed in this chapter, Ta-  
455 ble 2.1 summarizes the major chimera detection studies, their methodological  
456 approaches, and their known limitations. This consolidated comparison brings to-  
457 gether reference-based approaches, de novo strategies, alignment-driven tools, en-  
458 semble machine-learning systems, and general ML-based sequence-quality frame-  
459 works. Presenting these methods side-by-side clarifies their performance bound-  
460 aries and highlights the unresolved challenges that persist in mitochondrial genome  
461 analysis and chimera detection.

Table 2.1: Summary of Existing Methods and Research  
Gaps

Method/Study	Scope/Approach	Limitations
Reference-based Chimera Detection	Compares query sequences against curated, non-chimeric reference databases; identifies mosaic sequences by evaluating similarity to known templates.	Depends heavily on completeness and quality of reference databases; often fails when novel taxa or missing parent sequences are present; reduced accuracy for low-divergence chimeras.
De novo Chimera Detection	Identifies chimeras using only internal dataset relationships; relies on abundance patterns and compositional similarity; reconstructs sequences as mosaics of high-abundance parents.	Assumes true sequences are more abundant—fails when amplification bias distorts abundance; struggles with evenly abundant parental sequences; can misclassify highly similar true variants.

Method/Study	Scope/Approach	Limitations
UCHIME	Alignment-based chimera detection; segments query sequence, identifies parent candidates, performs 3-way alignment, and computes chimera scores; supports both reference-based and de novo modes.	Accuracy inflated in original benchmarks; suffers under incomplete databases; poor performance on low-divergence chimeras; sensitive to sequencing errors; misclassifies when parents are missing.
UCHIME2	Improved uncertainty handling; classifies ambiguous sequences as unknown; offers multiple sensitivity/specificity modes; more robust with incomplete references; higher sensitivity (93–99%).	Cannot achieve perfect accuracy due to “perfect fake models”; genuine variants may be indistinguishable from artificial recombinants; theoretical detection limit remains.
CATCh	First ML ensemble tool for 16S chimera detection; integrates outputs of UCHIME, ChimeraSlayer, DECIPHER, Pintail, Perseus via SVM classifier; significantly improves sensitivity and specificity.	Depends on performance of underlying tools; ML model limited to features they output; ensemble can still misclassify in datasets with extreme novelty or low coverage.

Method/Study	Scope/Approach	Limitations
ChimPipe	Pipeline for detecting fusion genes and transcript-derived chimeras in RNA-seq; uses discordant paired-end reads and split-alignments; predicts isoforms and breakpoint coordinates.	Designed for RNA-seq, not amplicons; needs high-quality genome and annotation; computationally heavier; limited to organisms with reference genomes.
Machine-Learning Sequence Quality & Chimera Detection (general)	Uses k-mer profiles, GC content shifts, entropy, split-read statistics, mapping quality variation, and micro-homology signatures as predictive features; identifies subtle artifacts missed by heuristics.	Requires labeled training data; model performance depends on feature engineering; may capture dataset-specific biases; limited generalization if training data is narrow or unrepresentative.

462 Across existing studies, no single approach reliably detects all forms of chimeric  
 463 sequences, particularly those generated by PCR-induced template switching in  
 464 mitochondrial genomes. Reference-based tools perform poorly when parental se-  
 465 quences are absent; de novo methods rely strongly on abundance assumptions;  
 466 alignment-based systems show reduced sensitivity to low-divergence chimeras; and  
 467 ensemble methods inherit the limitations of their component algorithms. RNA-  
 468 seq-oriented pipelines likewise do not generalize well to organelle data. Although  
 469 machine learning approaches offer promising feature-based detection, they are  
 470 rarely applied to mitochondrial genomes and are not trained specifically on PCR-

471 induced organelle chimeras. These limitations indicate a clear research gap: the  
472 need for a specialized, feature-driven classifier tailored to mitochondrial PCR-  
473 induced chimeras that integrates k-mer composition, split-alignment signals, and  
474 micro-homology features to achieve more accurate detection than current heuristic  
475 or alignment-based tools.

## 476 Chapter 3

# 477 Research Methodology

478 This chapter outlines and explains the specific steps and activities to be carried  
479 out in completing the project.

### 480 3.1 Research Activities

481 As illustrated in Figure 3.1, the researchers will carry out a sequence of compu-  
482 tational procedures designed to detect PCR-induced chimeric reads in mitochon-  
483 drial genomes. The process begins with the collection of mitochondrial reference  
484 sequences from the NCBI database, which will serve as the foundation for gener-  
485 ating simulated chimeric reads. These datasets will then undergo bioinformatics  
486 pipeline development, which includes alignment, k-mer extraction, and homology-  
487 based filtering to prepare the data for model construction. The machine-learning  
488 model will subsequently be trained and tested using the processed datasets to  
489 assess its accuracy and reliability. Depending on the evaluation results, the model

490 will either be refined and retrained to improve performance or, if the metrics meet  
 491 the desired threshold, deployed for further validation and application.

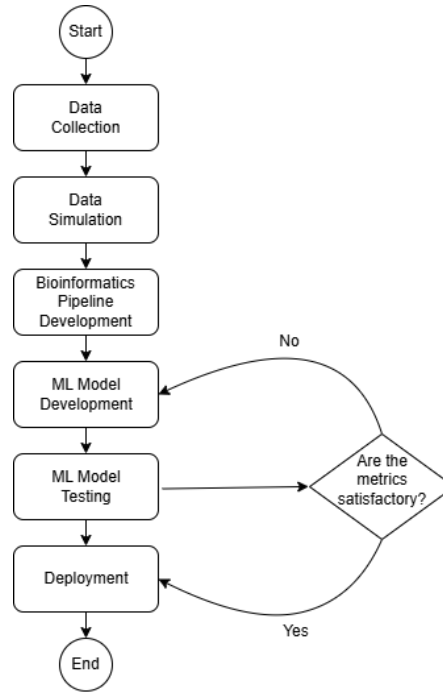

Figure 3.1: Process Diagram of Special Project

### 492 3.1.1 Data Collection

493 The researchers will collect mitochondrial genome reference sequences of *Sar-*  
 494 *dinella lemuru* from the National Center for Biotechnology Information (NCBI)  
 495 database. The downloaded files will be in FASTA format to ensure compatibility  
 496 with bioinformatics tools and subsequent analysis. The gathered sequences will  
 497 serve as the basis for generating simulated chimeric reads to be used in model  
 498 development.

499 The expected outcome of this process is a comprehensive dataset of *Sardinella*

500 *lemuru* mitochondrial reference sequences that will serve as the foundation for  
501 the succeeding stages of the study. This step is scheduled to start in the first  
502 week of November 2025 and is expected to be completed by the last week of  
503 November 2025, with a total duration of approximately one (1) month.

### 504 **3.1.2 Data Simulation**

505 The researchers will simulate sequencing data using the reference sequences col-  
506 lected from NCBI. Using `wgsim`, a total of 5,000 paired-end reads (R1 and R2)  
507 will be generated from the reference genome and designated as clean reads. These  
508 reads will be saved in FASTQ (`.fastq`) format. From the same reference, a Bash  
509 script will be created to deliberately cut and reconnect portions of the sequence,  
510 introducing artificial junctions that mimic chimeric regions. The manipulated  
511 reference file, saved in FASTA (`.fasta`) format, will then be processed in `wgsim`  
512 to simulate an additional 5,000 paired-end chimeric reads, also stored in FASTQ  
513 (`.fastq`) format. The resulting read files will be aligned to the original reference  
514 genome using SAMtools, generating SAM (`.sam`) or BAM (`.bam`) alignment files.  
515 During this alignment process, clean reads will be labeled as “0,” while chimeric  
516 reads will be labeled as “1” in a corresponding CSV (`.tsv`) file.

517 The expected outcome of this process is a complete set of clean and chimeric  
518 paired-end reads prepared for subsequent analysis and model development. This  
519 step is scheduled to start in the first week of November 2025 and is expected  
520 to be completed by the last week of November 2025, with a total duration of  
521 approximately one (1) month.

### 522 3.1.3 Bioinformatics Tools Pipeline

523 The researchers will obtain the necessary analytical features through the devel-  
524 opment and implementation of a bioinformatics pipeline. This pipeline will serve  
525 as a reproducible and modular workflow that accepts FASTQ and BAM inputs,  
526 processes these through a series of analytical stages, and outputs tabular feature  
527 matrices (TSV) for downstream machine learning. All scripts will be version-  
528 controlled through GitHub, and computational environments will be standardized  
529 using Conda to ensure cross-platform reproducibility. To promote transparency  
530 and replicability, the exact software versions, parameters, and command-line ar-  
531 guments used in each stage will be documented. To further ensure correctness  
532 and adherence to best practices, the researchers will consult with bioinformatics  
533 experts in Philippine Genome Center Visayas for validation of pipeline design,  
534 feature extraction logic, and overall data integrity. This stage of the study is  
535 scheduled to begin in the last week of November 2025 and conclude by the last  
536 week of January 2026, with an estimated total duration of approximately two (2)  
537 months.

538 The bioinformatics pipeline focuses on three principal features from the sim-  
539 ulated and aligned sequencing data: (1) supplementary alignment count (SA  
540 count), (2) k-mer composition difference between read segments, and (3) micro-  
541 homology length at potential junctions. Each of these features captures a distinct  
542 biological or computational signature associated with PCR-induced chimeras.

## 543 Alignment and Supplementary Alignment Count

544 This will be derived through sequence alignment using Minimap2, with subsequent  
545 processing performed using SAMtools and `pysam` in Python. Sequencing reads  
546 will be aligned to the *Sardinella lemuru* mitochondrial reference genome using  
547 Minimap2 with the `-ax sr` preset (optimized for short reads). The output will  
548 be converted and sorted using SAMtools, producing an indexed BAM file which  
549 will be parsed using `pysam` to count the number of supplementary alignments  
550 (SA tags) per read. Each read's mapping quality, number of split segments,  
551 and alignment characteristics will be recorded in a corresponding TSV file. The  
552 presence of multiple alignment loci within a single read, as reflected by a nonzero  
553 SA count, serves as direct computational evidence of chimerism. Reads that  
554 contain supplementary alignments or soft-clipped regions are strong candidates  
555 for chimeric artifacts arising from PCR template switching or improper assembly  
556 during sequencing.

## 557 K-mer Composition Difference

558 Chimeric reads often comprise fragments from distinct genomic regions, resulting  
559 in a compositional discontinuity between segments. Comparing k-mer frequency  
560 profiles between the left and right halves of a read allows detection of such abrupt  
561 compositional shifts, independent of alignment information. This will be obtained  
562 using Jellyfish, a fast k-mer counting software. For each read, the sequence will  
563 be divided into two segments, either at the midpoint or at empirically determined  
564 breakpoints inferred from supplementary alignment data, to generate left and right  
565 sequence segments. Jellyfish will then compute k-mer frequency profiles (with  $k =$

566 5 or 6) for each segment. The resulting k-mer frequency vectors will be normalized  
567 and compared using distance metrics such as cosine similarity or Jensen–Shannon  
568 divergence to quantify compositional disparity between the two halves of the same  
569 read. The resulting difference scores will be stored in a structured TSV file.

## 570 **Micro-homology Length**

571 The micro-homology length will be computed using a custom Python script that  
572 detects the longest exact suffix–prefix overlap within  $\pm 30$  base pairs surround-  
573 ing a candidate breakpoint. This analysis identifies the number of consecutive  
574 bases shared between the end of one segment and the beginning of another. The  
575 presence and length of such micro-homology are classic molecular signatures of  
576 PCR-induced template switching, where short identical regions (typically 3–15  
577 base pairs) promote premature termination and recombination of DNA synthesis  
578 on a different template strand. By quantifying micro-homology, the researchers  
579 can assess whether the suspected breakpoint exhibits characteristics consistent  
580 with PCR artifacts rather than true biological variants. Each read will therefore  
581 be annotated with its corresponding micro-homology length, overlap sequence,  
582 and GC content.

583 After extracting the three primary features, all resulting TSV files will be  
584 joined using the read identifier as a common key to generate a unified feature ma-  
585 trix. Additional read-level metadata such as read length, mean base quality, and  
586 number of clipped bases will also be included to provide contextual information.  
587 This consolidated dataset will serve as the input for subsequent machine-learning  
588 model development and evaluation.

### 589 3.1.4 Machine-Learning Model Development

590 The classification component of MitoChime will employ two ensemble algo-  
591 rithms—Random Forest (RF) and Extreme Gradient Boosting (XGBoost)—to  
592 evaluate complementary learning paradigms. Random Forest applies bootstrap  
593 aggregation (bagging) to reduce model variance and improve stability, whereas  
594 XGBoost implements gradient boosting to minimize bias and capture complex  
595 non-linear relationships among genomic features. Using both models enables a  
596 balanced assessment of predictive performance and interpretability.

597 The dataset will be divided into training (80%) and testing (20%) subsets.  
598 The training data will be used for model fitting and hyperparameter optimization  
599 through five-fold cross-validation, in which the data are partitioned into five folds;  
600 four folds are used for training and one for validation in each iteration. Perfor-  
601 mance metrics will be averaged across folds, and the optimal parameters will be  
602 selected based on mean cross-validation accuracy. The final models will then be  
603 evaluated on the held-out test set to obtain unbiased performance estimates.

604 Model development and evaluation will be implemented in Python (ver-  
605 sion 3.11) using the `scikit-learn` and `xgboost` libraries. Standard metrics  
606 including accuracy, precision, recall, F1-score, and area under the ROC curve  
607 (AUC) will be computed to quantify predictive performance. Feature-importance  
608 analyses will be performed to identify the most discriminative variables contribut-  
609 ing to chimera detection.

### 610 **3.1.5 Validation and Testing**

611 Validation will involve both internal and external evaluations. Internal validation  
612 will be achieved through five-fold cross-validation on the training data to verify  
613 model generalization and reduce variance due to random sampling. External  
614 validation will be achieved through testing on the 20% hold-out dataset derived  
615 from the simulated reads, which will serve as an unbiased benchmark to evaluate  
616 how well the trained models generalize to unseen data. All feature extraction and  
617 preprocessing steps will be performed using the same bioinformatics pipeline to  
618 ensure consistency and comparability across validation stages.

619 Comparative evaluation between the Random Forest and XGBoost classifiers  
620 will establish which model achieves superior predictive accuracy and computa-  
621 tional efficiency under identical data conditions.

### 622 **3.1.6 Documentation**

623 Comprehensive documentation will be maintained throughout the study to en-  
624 sure transparency, reproducibility, and scientific integrity. All stages of the re-  
625 search—including data acquisition, preprocessing, feature extraction, model train-  
626 ing, and validation—will be systematically recorded. For each analytical step, the  
627 corresponding parameters, software versions, and command-line scripts will be  
628 documented to enable exact replication of results.

629 Version control and collaborative management will be implemented through  
630 GitHub, which will serve as the central repository for all project files, including  
631 Python scripts, configuration settings, and Jupyter notebooks. The repository

structure will follow standard research data management practices, with clear directories for datasets, processed outputs, and analysis scripts. Changes will be tracked through commit histories to ensure traceability and accountability.

Computational environments will be standardized using Conda, with environment files specifying dependencies and package versions to maintain consistency across systems. Experimental workflows and exploratory analyses will be conducted in Jupyter Notebooks, which facilitate real-time visualization, annotation, and incremental testing of results.

For the preparation of the final manuscript and supplementary materials, Overleaf (LaTeX) will be utilized to produce publication-quality formatting, consistent referencing, and reproducible document compilation. The documentation process will also include a project timeline outlining major milestones such as data collection, simulation, feature extraction, model evaluation, and reporting to ensure systematic progress and adherence to the research schedule.

## 3.2 Calendar of Activities

Table 3.1 presents the project timeline in the form of a Gantt chart, where each bullet point corresponds to approximately one week of planned activity.
